# The role of the parser

Parser

- performs context-free syntax analysis
- guides context-sensitive analysis
- constructs an intermediate representation
- produces meaningful error messages
- attempts error correction

For the next few weeks, we will look at parser construction

Syntax analysis

Context-free syntax is specified with a *context-free grammar*.

Formally, a CFG G is a 4-tuple (V_n, V_t, P, S), where:

V_n, the *nonterminals*, is a set of syntactic variables that denote sets of (sub)strings occurring in the language.
These are used to impose a structure on the grammar.

V_t is the set of *terminal* symbols in the grammar.
For our purposes, V_t is the set of tokens returned by the scanner.

P is a finite set of *productions* specifying how terminals and non-terminals can be combined to form strings in the language.
Each production must have a single non-terminal on its left hand side.

S is a distinguished nonterminal $(S \in V_n)$ denoting the entire set of strings in $L(G)$.
This is sometimes called a *goal symbol*.

The set $V = V_t \cup V_n$ is called the *vocabulary* of G

Notation and terminology

- $a, b, c, \ldots \in V_t$

- $A, B, C, \ldots \in V_n$

- $U, V, W, \ldots \in V$

- $\alpha, \beta, \gamma, \ldots \in V^*$

- $u, v, w, \ldots \in V_t^*$

If $A \to \gamma$ then $\alpha A \beta \Rightarrow \alpha \gamma \beta$ is a *single-step derivation* using $A \to \gamma$

Similarly, $\Rightarrow^*$ and $\Rightarrow^+$ denote derivations of ≥ 0 and ≥ 1 steps

If $S \Rightarrow^* \beta$ then β is said to be a *sentential form* of G

$L(G) = \{w \in V_t^* \mid S \Rightarrow^+ w\}$, $w \in L(G)$ is called a *sentence* of G

Note, $L(G) = \{\beta \in V^* \mid S \Rightarrow^* \beta\} \cap V_t^*$

Syntax analysis

Grammars are often written in Backus-Naur form (BNF).

Example:

$$
\begin{array}{r|lll}
1 & \langle\text{goal}\rangle & ::= & \langle\text{expr}\rangle \\
2 & \langle\text{expr}\rangle & ::= & \langle\text{expr}\rangle\langle\text{op}\rangle\langle\text{expr}\rangle \\
3 & & | & \texttt{num} \\
4 & & | & \texttt{id} \\
5 & \langle\text{op}\rangle & ::= & + \\
6 & & | & - \\
7 & & | & * \\
8 & & | & / \\
\end{array}
$$

This describes simple expressions over numbers and identifiers.

In a BNF for a grammar, we represent

1. non-terminals with angle brackets or capital letters
2. terminals with `typewriter` font or <u>underline</u>
3. productions as in the example

Scanning vs. parsing

Where do we draw the line?

$$
\begin{aligned}
term &::= & &[\mathrm{a}-\mathrm{z}\mathrm{A}-\mathrm{z}]([\mathrm{a}-\mathrm{z}\mathrm{A}-\mathrm{z}] \mid [0-9])^* \\
     &   & \mid\ & 0 \mid [1-9][0-9]^* \\
op   &::= & &+ \mid - \mid * \mid / \\
expr &::= & &(term\ op)^*\, term
\end{aligned}
$$

Regular expressions are used to classify:

- identifiers, numbers, keywords
- REs are more concise and simpler for tokens than a grammar
- more efficient scanners can be built from REs (DFAs) than grammars

Context-free grammars are used to count:

- brackets: `()`, `begin...end`, `if...then...else`
- imparting structure: expressions

Syntactic analysis is complicated enough: grammar for C has around 200 productions. Factoring out lexical analysis as a separate phase makes compiler more manageable.

Derivations

We can view the productions of a CFG as rewriting rules.

Using our example CFG:

$$
\begin{aligned}
\langle goal \rangle \;\Rightarrow\;& \langle expr \rangle \\
\Rightarrow\;& \langle expr \rangle \langle op \rangle \langle expr \rangle \\
\Rightarrow\;& \langle expr \rangle \langle op \rangle \langle expr \rangle \langle op \rangle \langle expr \rangle \\
\Rightarrow\;& \langle id,x \rangle \langle op \rangle \langle expr \rangle \langle op \rangle \langle expr \rangle \\
\Rightarrow\;& \langle id,x \rangle + \langle expr \rangle \langle op \rangle \langle expr \rangle \\
\Rightarrow\;& \langle id,x \rangle + \langle num,2 \rangle \langle op \rangle \langle expr \rangle \\
\Rightarrow\;& \langle id,x \rangle + \langle num,2 \rangle * \langle expr \rangle \\
\Rightarrow\;& \langle id,x \rangle + \langle num,2 \rangle * \langle id,y \rangle
\end{aligned}
$$

We have derived the sentence `x + 2 * y`.
We denote this $\langle goal \rangle \Rightarrow^* $ `id + num * id`.

Such a sequence of rewrites is a *derivation* or a *parse*.

The process of discovering a derivation is called *parsing*.

Derivations

At each step, we chose a non-terminal to replace.

This choice can lead to different derivations.

Two are of particular interest:

leftmost derivation
the leftmost non-terminal is replaced at each step

rightmost derivation
the rightmost non-terminal is replaced at each step

The previous example was a leftmost derivation.

Rightmost derivation

For the string $\mathtt{x} + \mathtt{2} * \mathtt{y}$:
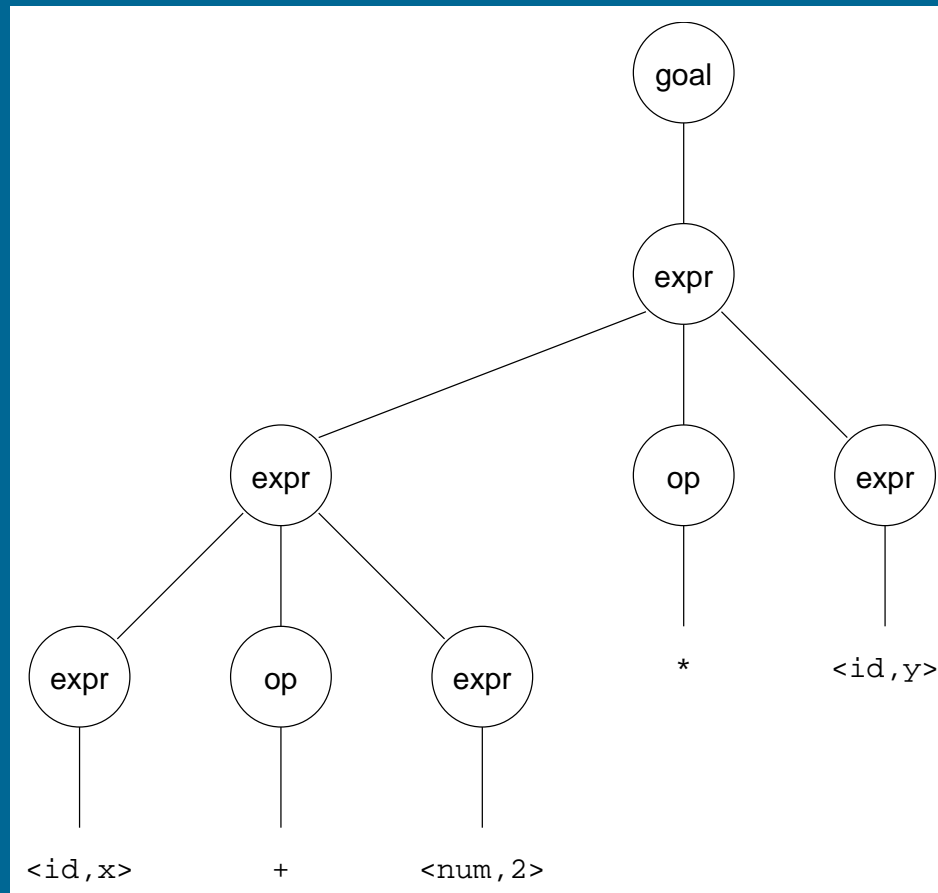

$$
\begin{aligned}
\langle\text{goal}\rangle \;\Rightarrow\;& \langle\text{expr}\rangle \\
\Rightarrow\;& \langle\text{expr}\rangle\langle\text{op}\rangle\langle\text{expr}\rangle \\
\Rightarrow\;& \langle\text{expr}\rangle\langle\text{op}\rangle\langle\text{id,y}\rangle \\
\Rightarrow\;& \langle\text{expr}\rangle * \langle\text{id,y}\rangle \\
\Rightarrow\;& \langle\text{expr}\rangle\langle\text{op}\rangle\langle\text{expr}\rangle * \langle\text{id,y}\rangle \\
\Rightarrow\;& \langle\text{expr}\rangle\langle\text{op}\rangle\langle\text{num,2}\rangle * \langle\text{id,y}\rangle \\
\Rightarrow\;& \langle\text{expr}\rangle + \langle\text{num,2}\rangle * \langle\text{id,y}\rangle \\
\Rightarrow\;& \langle\text{id,x}\rangle + \langle\text{num,2}\rangle * \langle\text{id,y}\rangle
\end{aligned}
$$

Again, $\langle\text{goal}\rangle \Rightarrow^* \mathtt{id} + \mathtt{num} * \mathtt{id}$.

Precedence

Treewalk evaluation computes $(\mathrm{x} + 2) * \mathrm{y}$
— the "wrong" answer!

Should be $\mathrm{x} + (2 * \mathrm{y})$

Precedence

These two derivations point out a problem with the grammar.

It has no notion of precedence, or implied order of evaluation.

To add precedence takes additional machinery:

$$
\begin{array}{r|lll}
1 & \langle\text{goal}\rangle & ::= & \langle\text{expr}\rangle \\
2 & \langle\text{expr}\rangle & ::= & \langle\text{expr}\rangle + \langle\text{term}\rangle \\
3 & & | & \langle\text{expr}\rangle - \langle\text{term}\rangle \\
4 & & | & \langle\text{term}\rangle \\
5 & \langle\text{term}\rangle & ::= & \langle\text{term}\rangle * \langle\text{factor}\rangle \\
6 & & | & \langle\text{term}\rangle / \langle\text{factor}\rangle \\
7 & & | & \langle\text{factor}\rangle \\
8 & \langle\text{factor}\rangle & ::= & \texttt{num} \\
9 & & | & \texttt{id}
\end{array}
$$

This grammar enforces a precedence on the derivation:

- terms *must* be derived from expressions
- forces the "correct" tree

Now, for the string $x + 2 * y$:
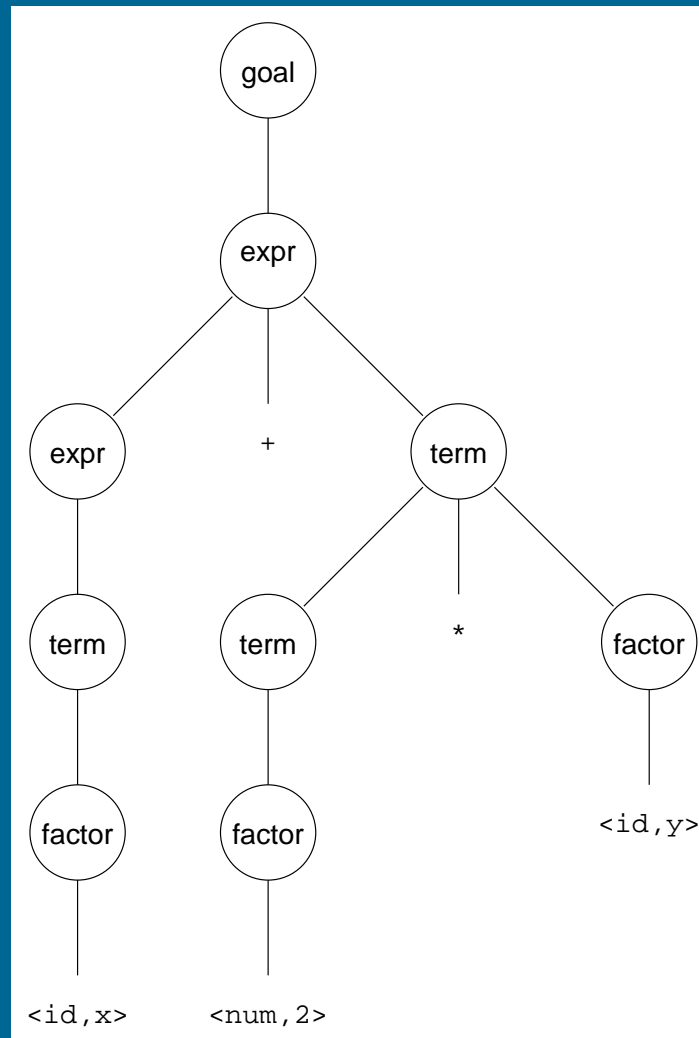

$$
\begin{aligned}
\langle goal \rangle \;\; & \Rightarrow \;\; \langle expr \rangle \\
& \Rightarrow \;\; \langle expr \rangle + \langle term \rangle \\
& \Rightarrow \;\; \langle expr \rangle + \langle term \rangle * \langle factor \rangle \\
& \Rightarrow \;\; \langle expr \rangle + \langle term \rangle * \langle id,y \rangle \\
& \Rightarrow \;\; \langle expr \rangle + \langle factor \rangle * \langle id,y \rangle \\
& \Rightarrow \;\; \langle expr \rangle + \langle num,2 \rangle * \langle id,y \rangle \\
& \Rightarrow \;\; \langle term \rangle + \langle num,2 \rangle * \langle id,y \rangle \\
& \Rightarrow \;\; \langle factor \rangle + \langle num,2 \rangle * \langle id,y \rangle \\
& \Rightarrow \;\; \langle id,x \rangle + \langle num,2 \rangle * \langle id,y \rangle
\end{aligned}
$$

Again, $\langle goal \rangle \Rightarrow^* id + num * id$, but this time, we build the desired tree.

Precedence

Treewalk evaluation computes $x + (2 * y)$

Ambiguity

If a grammar has more than one derivation for a single sentential form, then it is *ambiguous*

Example:

$$\langle\text{stmt}\rangle \quad ::= \quad \texttt{if } \langle\text{expr}\rangle\texttt{then } \langle\text{stmt}\rangle$$
$$| \quad \texttt{if } \langle\text{expr}\rangle\texttt{then } \langle\text{stmt}\rangle\texttt{else } \langle\text{stmt}\rangle$$
$$| \quad \texttt{other stmts}$$

Consider deriving the sentential form:

$$\texttt{if } E_1 \texttt{ then if } E_2 \texttt{ then } S_1 \texttt{ else } S_2$$

It has two derivations.

This ambiguity is purely grammatical.

It is a *context-free* ambiguity.

Ambiguity

May be able to eliminate ambiguities by rearranging the grammar:

$\langle$stmt$\rangle$ ::= $\langle$matched$\rangle$
| $\langle$unmatched$\rangle$
$\langle$matched$\rangle$ ::= `if` $\langle$expr$\rangle$ `then` $\langle$matched$\rangle$ `else` $\langle$matched$\rangle$
| `other stmts`
$\langle$unmatched$\rangle$ ::= `if` $\langle$expr$\rangle$ `then` $\langle$stmt$\rangle$
| `if` $\langle$expr$\rangle$ `then` $\langle$matched$\rangle$ `else` $\langle$unmatched$\rangle$

This generates the same language as the ambiguous grammar, but applies the common sense rule:

match each `else` *with the closest unmatched* `then`

This is most likely the language designer's intent.

Ambiguity

Ambiguity is often due to confusion in the context-free specification.

Context-sensitive confusions can arise from *overloading*.

Example:

```
a = f(17)
```

In many Algol-like languages, f could be a function or subscripted variable.
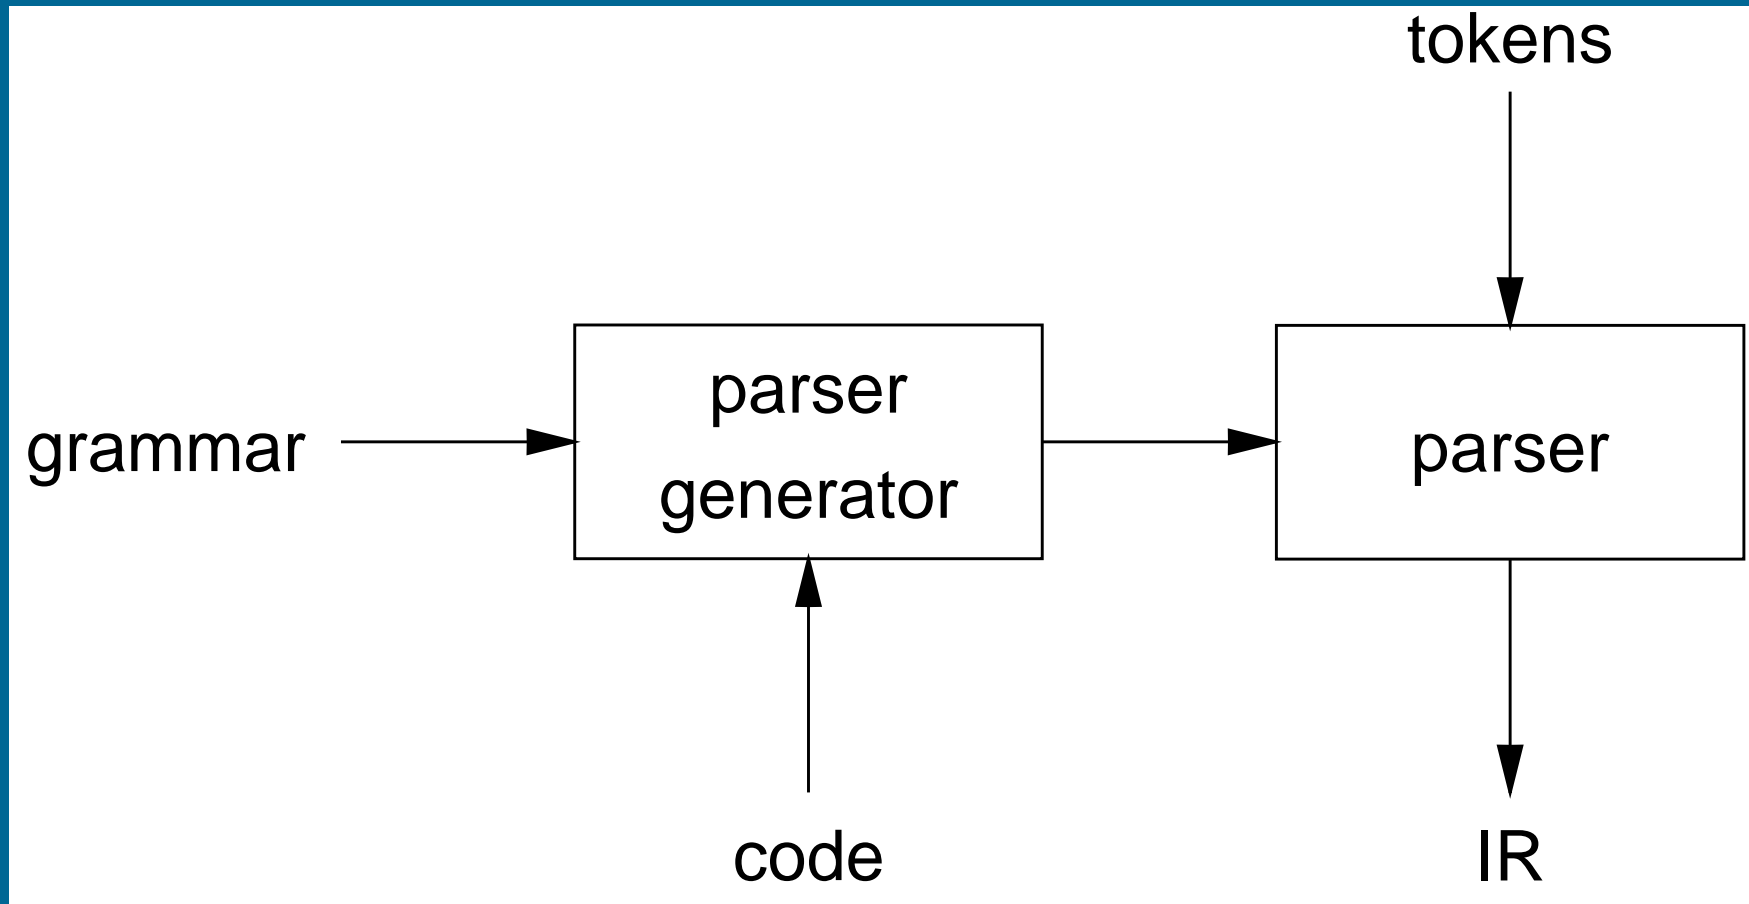

Disambiguating this statement requires context:

- need *values* of declarations
- not *context-free*
- really an issue of *type*

Rather than complicate parsing, we will handle this separately.

Our goal is a flexible parser generator system

Top-down versus bottom-up

Top-down parsers

- start at the root of derivation tree and fill in
- picks a production and tries to match the input
- may require backtracking
- some grammars are backtrack-free (*predictive*)

Bottom-up parsers

- start at the leaves and fill in
- start in a state valid for legal first tokens
- as input is consumed, change state to encode possibilities (*recognize valid prefixes*)
- use a stack to store both state and sentential forms

Top-down parsing

A top-down parser starts with the root of the parse tree, labelled with the start or goal symbol of the grammar.

To build a parse, it repeats the following steps until the fringe of the parse tree matches the input string

1. At a node labelled A, select a production $A \rightarrow \alpha$ and construct the appropriate child for each symbol of α

2. When a terminal is added to the fringe that doesn't match the input string, backtrack

3. Find the next node to be expanded (must have a label in V_n)

The key is selecting the right production in step 1

$\Rightarrow$ should be guided by input string

Simple expression grammar

Recall our grammar for simple expressions:

$$
\begin{array}{r|lcl}
1 & \langle goal \rangle & ::= & \langle expr \rangle \\
2 & \langle expr \rangle & ::= & \langle expr \rangle + \langle term \rangle \\
3 & & | & \langle expr \rangle - \langle term \rangle \\
4 & & | & \langle term \rangle \\
5 & \langle term \rangle & ::= & \langle term \rangle * \langle factor \rangle \\
6 & & | & \langle term \rangle / \langle factor \rangle \\
7 & & | & \langle factor \rangle \\
8 & \langle factor \rangle & ::= & \texttt{num} \\
9 & & | & \texttt{id}
\end{array}
$$

Consider the input string $x - 2 * y$

Prod'n	Sentential form	Input
–	⟨goal⟩	↑x – 2 * y
1	⟨expr⟩	↑x – 2 * y
2	⟨expr⟩ + ⟨term⟩	↑x – 2 * y
4	⟨term⟩ + ⟨term⟩	↑x – 2 * y
7	⟨factor⟩ + ⟨term⟩	↑x – 2 * y
9	id + ⟨term⟩	↑x – 2 * y
–	id + ⟨term⟩	x ↑– 2 * y
–	⟨expr⟩	↑x – 2 * y
3	⟨expr⟩ – ⟨term⟩	↑x – 2 * y
4	⟨term⟩ – ⟨term⟩	↑x – 2 * y
7	⟨factor⟩ – ⟨term⟩	↑x – 2 * y
9	id – ⟨term⟩	↑x – 2 * y
–	id – ⟨term⟩	x ↑– 2 * y
–	id – ⟨term⟩	x – ↑2 * y
7	id – ⟨factor⟩	x – ↑2 * y
8	id – num	x – ↑2 * y
–	id – num	x – 2 ↑* y
–	id – ⟨term⟩	x – ↑2 * y
5	id – ⟨term⟩ * ⟨factor⟩	x – ↑2 * y
7	id – ⟨factor⟩ * ⟨factor⟩	x – ↑2 * y
8	id – num * ⟨factor⟩	x – ↑2 * y
–	id – num * ⟨factor⟩	x – 2 ↑* y
–	id – num * ⟨factor⟩	x – 2 * ↑y
9	id – num * id	x – 2 * ↑y
–	id – num * id	x – 2 * y ↑

Example

Another possible parse for $\mathtt{x} - 2 * \mathtt{y}$

Prod'n	Sentential form	Input
–	$\langle\text{goal}\rangle$	$\uparrow\mathtt{x} - 2 * \mathtt{y}$
1	$\langle\text{expr}\rangle$	$\uparrow\mathtt{x} - 2 * \mathtt{y}$
2	$\langle\text{expr}\rangle + \langle\text{term}\rangle$	$\uparrow\mathtt{x} - 2 * \mathtt{y}$
2	$\langle\text{expr}\rangle + \langle\text{term}\rangle + \langle\text{term}\rangle$	$\uparrow\mathtt{x} - 2 * \mathtt{y}$
2	$\langle\text{expr}\rangle + \langle\text{term}\rangle + \cdots$	$\uparrow\mathtt{x} - 2 * \mathtt{y}$
2	$\langle\text{expr}\rangle + \langle\text{term}\rangle + \cdots$	$\uparrow\mathtt{x} - 2 * \mathtt{y}$
2	$\cdots$	$\uparrow\mathtt{x} - 2 * \mathtt{y}$

If the parser makes the wrong choices, expansion doesn't terminate.

This isn't a good property for a parser to have.

(Parsers should terminate!)

Top-down parsing with pushdown automaton

A top-down parser for grammar $G = (V_n, V_t, P, S)$ is a pushdown automaton $A = (Q, V_t, V_k, \delta, q_0, k_0)$ that accepts input with empty pushdown where

- $Q = \{q_0\}$ is the set of states

- $V_k = V_n \cup V_t$ is the alphabet of pushdown symbols

- $\delta : Q \times V_t \cup \{\varepsilon\} \times V_k \to Q \times V_k^*$

- q_0 is the initial state

- $k_0 = S$ is the initial pushdown symbol

where

- $\delta(q_0, \varepsilon, A) = (q_0, \alpha)$ for each production $A \to \alpha \in P$

- $\delta(q_0, x, x) = (q_0, \varepsilon)$

Pushdown automaton example

Pushdown (rev)	Input	Prod'n
$\langle$goal$\rangle$	x-2*y	1
$\langle$expr$\rangle$	x-2*y	3
$\langle$term$\rangle - \langle$expr$\rangle$	x-2*y	4
$\langle$term$\rangle - \langle$term$\rangle$	x-2*y	7
$\langle$term$\rangle - \langle$factor$\rangle$	x-2*y	9
$\langle$term$\rangle -$ id	x-2*y	shift
$\langle$term$\rangle -$	-2*y	shift
$\langle$term$\rangle$	2*y	5
$\langle$factor$\rangle * \langle$term$\rangle$	2*y	7
$\langle$factor$\rangle * \langle$factor$\rangle$	2*y	8
$\langle$factor$\rangle *$ num	2*y	shift
$\langle$factor$\rangle *$	*y	shift
$\langle$factor$\rangle$	y	9
id	y	shift
		accepted

Left-recursion

Top-down parsers cannot handle left-recursion in a grammar

Formally, a grammar is *left-recursive* if

$$\exists A \in V_n \text{ such that } A \Rightarrow^+ A\alpha \text{ for some string } \alpha$$

Our simple expression grammar is left-recursive

Eliminating left-recursion

To remove left-recursion, we can transform the grammar

Consider the grammar fragment:

$$\langle \text{foo} \rangle \ ::= \ \langle \text{foo} \rangle \alpha$$
$$| \ \ \beta$$

where α and β do not start with $\langle \text{foo} \rangle$

We can rewrite this as:

$$\langle \text{foo} \rangle \ ::= \ \beta \langle \text{bar} \rangle$$
$$\langle \text{bar} \rangle \ ::= \ \alpha \langle \text{bar} \rangle$$
$$| \ \ \varepsilon$$

where $\langle \text{bar} \rangle$ is a new non-terminal

This fragment contains no left-recursion

Example

Our expression grammar contains two cases of left-recursion

$$
\begin{aligned}
\langle expr \rangle &::= \langle expr \rangle + \langle term \rangle \\
&\quad\mid\quad \langle expr \rangle - \langle term \rangle \\
&\quad\mid\quad \langle term \rangle \\
\langle term \rangle &::= \langle term \rangle * \langle factor \rangle \\
&\quad\mid\quad \langle term \rangle / \langle factor \rangle \\
&\quad\mid\quad \langle factor \rangle
\end{aligned}
$$

Applying the transformation gives

$$
\begin{aligned}
\langle expr \rangle &::= \langle term \rangle \langle expr' \rangle \\
\langle expr' \rangle &::= + \langle term \rangle \langle expr' \rangle \\
&\quad\mid\quad \varepsilon \\
&\quad\mid\quad - \langle term \rangle \langle expr' \rangle \\
\langle term \rangle &::= \langle factor \rangle \langle term' \rangle \\
\langle term' \rangle &::= * \langle factor \rangle \langle term' \rangle \\
&\quad\mid\quad \varepsilon \\
&\quad\mid\quad / \langle factor \rangle \langle term' \rangle
\end{aligned}
$$

With this grammar, a top-down parser will

- terminate
- backtrack on some inputs

Example

This cleaner grammar defines the same language

$$
\begin{array}{r|lcl}
1 & \langle\text{goal}\rangle & ::= & \langle\text{expr}\rangle \\
2 & \langle\text{expr}\rangle & ::= & \langle\text{term}\rangle + \langle\text{expr}\rangle \\
3 & & | & \langle\text{term}\rangle - \langle\text{expr}\rangle \\
4 & & | & \langle\text{term}\rangle \\
5 & \langle\text{term}\rangle & ::= & \langle\text{factor}\rangle * \langle\text{term}\rangle \\
6 & & | & \langle\text{factor}\rangle / \langle\text{term}\rangle \\
7 & & | & \langle\text{factor}\rangle \\
8 & \langle\text{factor}\rangle & ::= & \texttt{num} \\
9 & & | & \texttt{id}
\end{array}
$$

It is

- right-recursive
- free of ε-productions

Unfortunately, it generates different associativity
Same syntax, different meaning

Example

Our long-suffering expression grammar:

$$
\begin{array}{r|lll}
1 & \langle goal \rangle & ::= & \langle expr \rangle \\
2 & \langle expr \rangle & ::= & \langle term \rangle \langle expr' \rangle \\
3 & \langle expr' \rangle & ::= & +\langle term \rangle \langle expr' \rangle \\
4 & & | & -\langle term \rangle \langle expr' \rangle \\
5 & & | & \varepsilon \\
6 & \langle term \rangle & ::= & \langle factor \rangle \langle term' \rangle \\
7 & \langle term' \rangle & ::= & *\langle factor \rangle \langle term' \rangle \\
8 & & | & /\langle factor \rangle \langle term' \rangle \\
9 & & | & \varepsilon \\
10 & \langle factor \rangle & ::= & \texttt{num} \\
11 & & | & \texttt{id}
\end{array}
$$

Recall, we factored out left-recursion

How much lookahead is needed?

We saw that top-down parsers may need to backtrack when they select the wrong production

Do we need arbitrary lookahead to parse CFGs?

- in general, yes
- use the Earley or Cocke-Younger, Kasami algorithms

Fortunately

- large subclasses of CFGs can be parsed with limited lookahead
- most programming language constructs can be expressed in a grammar that falls in these subclasses

Among the interesting subclasses are:

LL(1)**:** **l**eft to right scan, **l**eft-most derivation, **1**-token lookahead; and
LR(1)**:** **l**eft to right scan, **r**ight-most derivation, **1**-token lookahead

Predictive parsing

Basic idea:

> For any two productions $A \rightarrow \alpha \mid \beta$, we would like a distinct way of choosing the correct production to expand.

For $\alpha \in V^*$ and $k \in \mathbf{N}$, define $\text{FIRST}_k(\alpha)$ as the set of terminal strings of length less than or equal to k that appear first in a string derived from α. That is, if $\alpha \Rightarrow^* w \in V_t^*$, then $w|_k \in \text{FIRST}_k(\alpha)$. .

Key property:

Whenever two productions $A \rightarrow \alpha$ and $A \rightarrow \beta$ both appear in the grammar, we would like

$$\text{FIRST}_k(\alpha) \cap \text{FIRST}_k(\beta) = \phi$$

for some k. If $k = 1$, then the parser could make a correct choice with a lookahead of only one symbol!

The example grammar has this property!

Left factoring

What if a grammar does not have this property?

Sometimes, we can transform a grammar to have this property.

For each non-terminal A find the longest prefix α common to two or more of its alternatives.

if $\alpha \neq \varepsilon$ then replace all of the A productions
$A \rightarrow \alpha\beta_1 \mid \alpha\beta_2 \mid \cdots \mid \alpha\beta_n$
with
$$A \rightarrow \alpha A'$$
$$A' \rightarrow \beta_1 \mid \beta_2 \mid \cdots \mid \beta_n$$
where A' is a new non-terminal.

Repeat until no two alternatives for a single non-terminal have a common prefix.

Example

Consider a *right-recursive* version of the expression grammar:

$$
\begin{array}{r|lcl}
1 & \langle\text{goal}\rangle & ::= & \langle\text{expr}\rangle \\
2 & \langle\text{expr}\rangle & ::= & \langle\text{term}\rangle + \langle\text{expr}\rangle \\
3 & & | & \langle\text{term}\rangle - \langle\text{expr}\rangle \\
4 & & | & \langle\text{term}\rangle \\
5 & \langle\text{term}\rangle & ::= & \langle\text{factor}\rangle * \langle\text{term}\rangle \\
6 & & | & \langle\text{factor}\rangle / \langle\text{term}\rangle \\
7 & & | & \langle\text{factor}\rangle \\
8 & \langle\text{factor}\rangle & ::= & \texttt{num} \\
9 & & | & \texttt{id}
\end{array}
$$

To choose between productions 2, 3, & 4, the parser must see past the `num` or `id` and look at the $+$, $-$, $*$, or $/$.

$$\text{FIRST}_1(2) \cap \text{FIRST}_1(3) \cap \text{FIRST}_1(4) \neq \emptyset$$

This grammar *fails* the test.

Note: *This grammar is right-associative.*

Example

There are two nonterminals that must be left-factored:

$$
\begin{array}{rcl}
\langle\text{expr}\rangle & ::= & \langle\text{term}\rangle + \langle\text{expr}\rangle \\
& | & \langle\text{term}\rangle - \langle\text{expr}\rangle \\
& | & \langle\text{term}\rangle \\
\\
\langle\text{term}\rangle & ::= & \langle\text{factor}\rangle * \langle\text{term}\rangle \\
& | & \langle\text{factor}\rangle / \langle\text{term}\rangle \\
& | & \langle\text{factor}\rangle
\end{array}
$$

Applying the transformation gives us:

$$
\begin{array}{rcl}
\langle\text{expr}\rangle & ::= & \langle\text{term}\rangle\langle\text{expr}'\rangle \\
\langle\text{expr}'\rangle & ::= & +\langle\text{expr}\rangle \\
& | & -\langle\text{expr}\rangle \\
& | & \varepsilon \\
\\
\langle\text{term}\rangle & ::= & \langle\text{factor}\rangle\langle\text{term}'\rangle \\
\langle\text{term}'\rangle & ::= & *\langle\text{term}\rangle \\
& | & /\langle\text{term}\rangle \\
& | & \varepsilon
\end{array}
$$

Example

Substituting back into the grammar yields

$$
\begin{array}{r|lll}
1 & \langle goal \rangle & ::= & \langle expr \rangle \\
2 & \langle expr \rangle & ::= & \langle term \rangle \langle expr' \rangle \\
3 & \langle expr' \rangle & ::= & + \langle expr \rangle \\
4 & & | & - \langle expr \rangle \\
5 & & | & \varepsilon \\
6 & \langle term \rangle & ::= & \langle factor \rangle \langle term' \rangle \\
7 & \langle term' \rangle & ::= & * \langle term \rangle \\
8 & & | & / \langle term \rangle \\
9 & & | & \varepsilon \\
10 & \langle factor \rangle & ::= & \texttt{num} \\
11 & & | & \texttt{id}
\end{array}
$$

Now, selection requires only a single token lookahead.

Note: *This grammar is still right-associative.*

Example

	Sentential form	Input
–	$\langle$goal$\rangle$	$\uparrow$x $-$ 2 $*$ y
1	$\langle$expr$\rangle$	$\uparrow$x $-$ 2 $*$ y
2	$\langle$term$\rangle$$\langle$expr$'\rangle$	$\uparrow$x $-$ 2 $*$ y
6	$\langle$factor$\rangle$$\langle$term$'\rangle$$\langle$expr$'\rangle$	$\uparrow$x $-$ 2 $*$ y
11	id$\langle$term$'\rangle$$\langle$expr$'\rangle$	$\uparrow$x $-$ 2 $*$ y
–	id$\langle$term$'\rangle$$\langle$expr$'\rangle$	x $\uparrow$- 2 $*$ y
9	idε $\langle$expr$'\rangle$	x $\uparrow$- 2
4	id$-$ $\langle$expr$\rangle$	x $\uparrow$- 2 $*$ y
–	id$-$ $\langle$expr$\rangle$	x $-$ $\uparrow$2 $*$ y
2	id$-$ $\langle$term$\rangle$$\langle$expr$'\rangle$	x $-$ $\uparrow$2 $*$ y
6	id$-$ $\langle$factor$\rangle$$\langle$term$'\rangle$$\langle$expr$'\rangle$	x $-$ $\uparrow$2 $*$ y
10	id$-$ num$\langle$term$'\rangle$$\langle$expr$'\rangle$	x $-$ $\uparrow$2 $*$ y
–	id$-$ num$\langle$term$'\rangle$$\langle$expr$'\rangle$	x $-$ 2 $\uparrow*$ y
7	id$-$ num$*$ $\langle$term$\rangle$$\langle$expr$'\rangle$	x $-$ 2 $\uparrow*$ y
–	id$-$ num$*$ $\langle$term$\rangle$$\langle$expr$'\rangle$	x $-$ 2 $*$ $\uparrow$y
6	id$-$ num$*$ $\langle$factor$\rangle$$\langle$term$'\rangle$$\langle$expr$'\rangle$	x $-$ 2 $*$ $\uparrow$y
11	id$-$ num$*$ id$\langle$term$'\rangle$$\langle$expr$'\rangle$	x $-$ 2 $*$ $\uparrow$y
–	id$-$ num$*$ id$\langle$term$'\rangle$$\langle$expr$'\rangle$	x $-$ 2 $*$ y$\uparrow$
9	id$-$ num$*$ id$\langle$expr$'\rangle$	x $-$ 2 $*$ y$\uparrow$
5	id$-$ num$*$ id	x $-$ 2 $*$ y$\uparrow$

The next symbol determined each choice correctly.

Back to left-recursion elimination

Given a left-factored CFG, to eliminate left-recursion:

if $\exists\, A \to A\alpha$ then replace all of the A productions

$$A \to A\alpha \mid \beta \mid \ldots \mid \gamma$$

with

$$A \to NA'$$
$$N \to \beta \mid \ldots \mid \gamma$$
$$A' \to \alpha A' \mid \varepsilon$$

where N and A' are new productions.

Repeat until there are no left-recursive productions.

Generality

Question:

> By *left factoring* and *eliminating left-recursion*, can we transform an arbitrary context-free grammar to a form where it can be predictively parsed with a single token lookahead?

Answer:

> Given a context-free grammar that doesn't meet our conditions, it is undecidable whether an equivalent grammar exists that does meet our conditions.

Many *context-free languages* do not have such a grammar:

$$\{a^n 0 b^n \mid n \geq 1\} \bigcup \{a^n 1 b^{2n} \mid n \geq 1\}$$

Must look past an arbitrary number of a's to discover the 0 or the 1 and so determine the derivation.

Recursive descent parsing

General idea: Turn the grammar into a set of mutually recursive functions!

- Each non-terminal maps to a function

- The body of the function for $A \in V_n$ is determined by the productions
  $A \rightarrow \alpha_1 \mid \ldots \mid \alpha_k$

  – on function entry, use lookahead to determine the correct RHS
    $\alpha = \alpha_j$, say

  – in the body, generate code for each symbol of α in sequence

  – for a terminal symbol, the code consumes a matching input token

  – for a non-terminal symbol, the code invokes the non-terminal's function

Recursive descent parsing

In that manner, we can produce a simple recursive descent parser from the (right-associative) grammar.

```
goal:
    token ← next_token();
    if (expr() = ERROR | token ≠ EOF) then
        return ERROR;

expr:
    if (term() = ERROR) then
        return ERROR;
    else return expr_prime();

expr_prime:
    if (token = PLUS) then
        token ← next_token();
        return expr();
    else if (token = MINUS) then
        token ← next_token();
        return expr();
    else return OK;
```

Recursive descent parsing

```
term:
    if (factor() = ERROR) then
        return ERROR;
    else return term_prime();

term_prime:
    if (token = MULT) then
        token ← next_token();
        return term();
    else if (token = DIV) then
        token ← next_token();
        return term();
    else return OK;

factor:
    if (token = NUM) then
        token ← next_token();
        return OK;
    else if (token = ID) then
        token ← next_token();
        return OK;
    else return ERROR;
```

Building the tree

One of the key jobs of the parser is to build an intermediate representation of the source code.

To build an abstract syntax tree, we have each function return the AST for the word parsed by it. The function for a production gobbles up the ASTs for the non-terminal's on the RHS and applies the appropriate AST constructor.

Alternatively, the functions use an auxiliary stack for AST fragments.

Non-recursive predictive parsing

Observation:

> *Our recursive descent parser encodes state information in its run-time stack, or call stack.*

Using recursive procedure calls to implement a stack abstraction may not be particularly efficient.

This suggests other implementation methods:

- explicit stack, hand-coded parser
- stack-based, table-driven parser

Non-recursive predictive parsing

Now, a predictive parser looks like:

Rather than writing code, we build tables.

Building tables can be automated!

Table-driven parsers

A parser generator system often looks like:
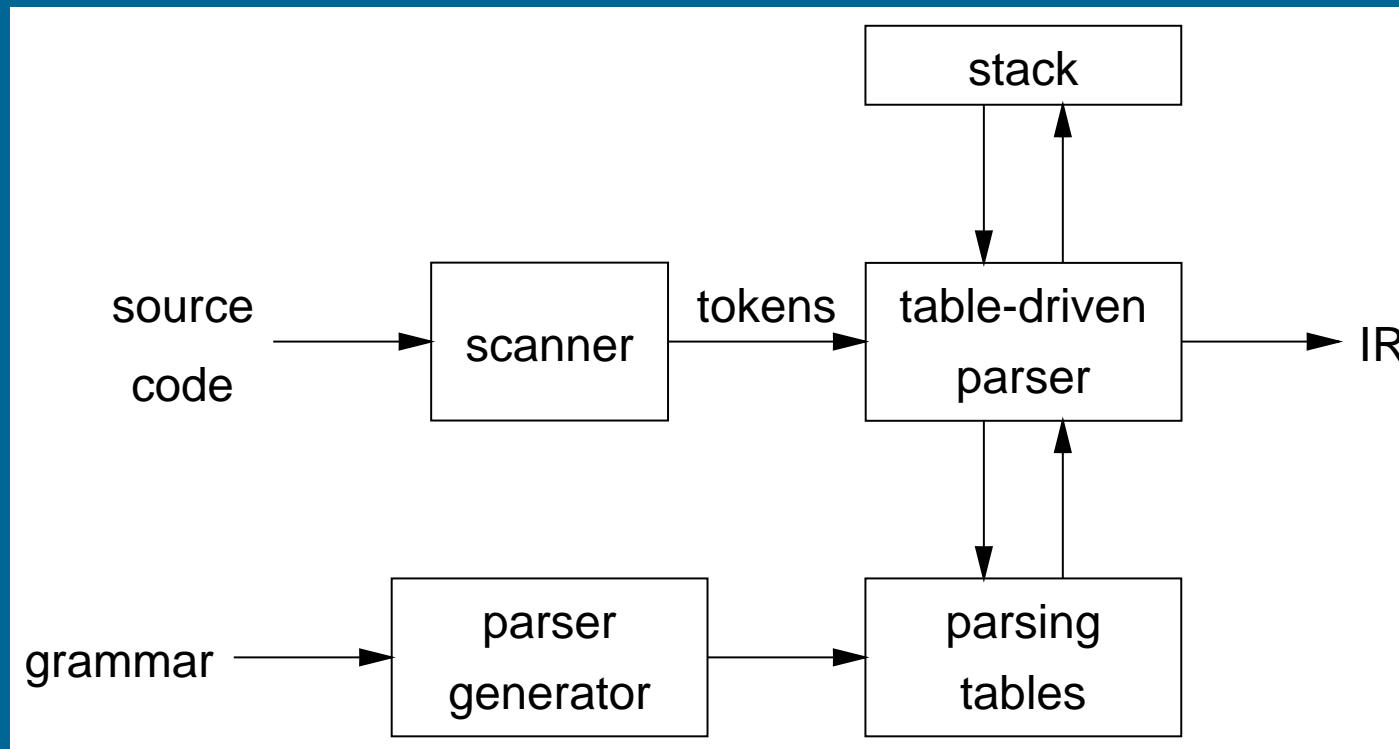

This is true for both top-down (LL) and bottom-up (LR) parsers

Non-recursive predictive parsing

Input: a string w and a parsing table M for G

```
tos ← 0
Stack[tos] ← EOF
Stack[++tos] ← Start Symbol
token ← next_token()

repeat
    X ← Stack[tos]
    if X is a terminal or EOF then
        if X = token then
            pop X
            token ← next_token()
        else error()
    else /* X is a non-terminal */
        if M[X,token] = X → Y₁Y₂···Yₖ then
            pop X
            push Yₖ,Yₖ₋₁,···,Y₁
        else error()
until X = EOF
```

Non-recursive predictive parsing

What we need now is a parsing table M.

Our expression grammar:

1	$\langle goal \rangle$	::=	$\langle expr \rangle$
2	$\langle expr \rangle$	::=	$\langle term \rangle \langle expr' \rangle$
3	$\langle expr' \rangle$	::=	$+\langle expr \rangle$
4			$\mid \quad -\langle expr \rangle$
5			$\mid \quad \varepsilon$
6	$\langle term \rangle$	::=	$\langle factor \rangle \langle term' \rangle$
7	$\langle term' \rangle$	::=	$*\langle term \rangle$
8			$\mid \quad /\langle term \rangle$
9			$\mid \quad \varepsilon$
10	$\langle factor \rangle$	::=	num
11			$\mid \quad$ id

Its parse table:

	id	num	$+$	$-$	$*$	$/$	$\$^{\dagger}$
$\langle goal \rangle$	1	1	–	–	–	–	–
$\langle expr \rangle$	2	2	–	–	–	–	–
$\langle expr' \rangle$	–	–	3	4	–	–	5
$\langle term \rangle$	6	6	–	–	–	–	–
$\langle term' \rangle$	–	–	9	9	7	8	9
$\langle factor \rangle$	11	10	–	–	–	–	–

[†] we use $ to represent EOF

Computing FIRST$=$ FIRST$_1$

For a string of grammar symbols α, define FIRST(α) as:

- the set of terminal symbols that begin strings derived from α:
  $$\{a \in V_t \mid \alpha \Rightarrow^* a\beta\}$$
- If $\alpha \Rightarrow^* \varepsilon$ then $\varepsilon \in$ FIRST(α)

FIRST(α) contains the set of tokens valid in the initial position in α

To compute FIRST(α) it is sufficient to know FIRST(X), for all $X \in V$:

$$\text{FIRST}(Y_1 Y_2 \ldots Y_k) = \text{FIRST}(Y_1) \oplus \text{FIRST}(Y_2) \oplus \ldots \oplus \text{FIRST}(Y_k)$$

where

$$M \oplus N = \left\{ \begin{array}{ll} M & \varepsilon \notin M \\ (M \setminus \{\varepsilon\}) \cup N & \varepsilon \in M \end{array} \right.$$

Clearly, FIRST$(a) = \{a\}$ for $a \in V_t$.

Computing FIRST

- Initialize $\mathrm{FIRST}(A) = \emptyset$, for all $A \in V_n$

- Repeat the following steps for all productions until no further additions can be made:

  1. If $A \to \varepsilon$ then:
     $\mathrm{FIRST}(A) \leftarrow \mathrm{FIRST}(A) \cup \{\varepsilon\}$
  2. If $A \to Y_1 Y_2 \cdots Y_k$:
     $\mathrm{FIRST}(A) \leftarrow \mathrm{FIRST}(A) \cup \left(\mathrm{FIRST}(Y_1) \oplus \mathrm{FIRST}(Y_2) \oplus \ldots \oplus \mathrm{FIRST}(Y_k)\right)$

FOLLOW

For a non-terminal A, define $\text{FOLLOW}(A)$ as

> the set of terminals that can appear immediately to the right of A
> in some sentential form

That is, $\text{FOLLOW}(A) = \{a \mid S\$ \Rightarrow^* \alpha A a \beta\}$

Thus, a non-terminal's FOLLOW set specifies the tokens that can legally appear after it, with \$ acting as end of input marker.

A terminal symbol has no FOLLOW set.

To build $\text{FOLLOW}(A)$:

1. Initialize $\text{FOLLOW}(A) = \emptyset$, for $A \in V_n$, $A \neq S$, and $\text{FOLLOW}(S) = \{\$\}$
2. Repeat the following steps for all productions $A \to \alpha B \beta$ until no further additions can be made:
   (a) $\text{FOLLOW}(B) \leftarrow \text{FOLLOW}(B) \cup (\text{FIRST}(\beta) - \{\varepsilon\})$
   (b) If $\varepsilon \in \text{FIRST}(\beta)$, then
   $\text{FOLLOW}(B) \leftarrow \text{FOLLOW}(B) \cup \text{FOLLOW}(A)$

LL(1) grammars

Previous definition

> A grammar G has a deterministic unambiguous predictive parser if for all non-terminals A, each distinct pair of productions $A \rightarrow \beta$ and $A \rightarrow \gamma$ satisfy the condition $\text{FIRST}(\beta) \bigcap \text{FIRST}(\gamma) = \phi$.

What if $A \Rightarrow^* \varepsilon$?

Revised definition

> A grammar G is LL(1) iff. for each set of productions
> $A \rightarrow \alpha_1 \mid \alpha_2 \mid \cdots \mid \alpha_n$:
>
> 1. $\text{FIRST}(\alpha_1), \text{FIRST}(\alpha_2), \ldots, \text{FIRST}(\alpha_n)$ are all pairwise disjoint
> 2. If $\alpha_i \Rightarrow^* \varepsilon$ then $\text{FIRST}(\alpha_j) \bigcap \text{FOLLOW}(A) = \phi, \forall 1 \leq j \leq n, i \neq j$.

If G is ε-free, condition 1 is sufficient.

LL(1) grammars

Provable facts about LL(1) grammars:

1. No left-recursive grammar is LL(1)

2. No ambiguous grammar is LL(1)

3. Some languages have no LL(1) grammar

4. An ε–free grammar where each alternative expansion for A begins with a distinct terminal is a *simple* LL(1) grammar.

Example

- $S \rightarrow aS \mid a$ is not LL(1) because $\text{FIRST}(aS) = \text{FIRST}(a) = \{a\}$

- $S \rightarrow aS'$
  $S' \rightarrow aS' \mid \varepsilon$
  accepts the same language and is LL(1)

LL(1) parse table construction

Input: Grammar G

Output: Parsing table M

Method:

1. $\forall$ productions $A \to \alpha$:

    (a) $\forall a \in \text{FIRST}(\alpha)$, add $A \to \alpha$ to $M[A, a]$

    (b) If $\varepsilon \in \text{FIRST}(\alpha)$:

    　i. $\forall b \in \text{FOLLOW}(A)$, add $A \to \alpha$ to $M[A, b]$

    　ii. If $\$ \in \text{FOLLOW}(A)$ then add $A \to \alpha$ to $M[A, \$]$

2. Set each undefined entry of M to `error`

If $\exists M[A, a]$ with multiple entries then grammar is not LL(1).

Note: recall $a, b \in V_t$, so $a, b \neq \varepsilon$

Example

Our long-suffering expression grammar:

$$S \to E \qquad\qquad T \to FT'$$
$$E \to TE' \qquad\qquad T' \to *T \mid /T \mid \varepsilon$$
$$E' \to +E \mid -E \mid \varepsilon \quad F \to \texttt{id} \mid \texttt{num}$$

	FIRST	FOLLOW
S	$\{\texttt{num}, \texttt{id}\}$	$\{\$\}$
E	$\{\texttt{num}, \texttt{id}\}$	$\{\$\}$
E'	$\{\varepsilon, +, -\}$	$\{\$\}$
T	$\{\texttt{num}, \texttt{id}\}$	$\{+, -, \$\}$
T'	$\{\varepsilon, *, /\}$	$\{+, -, \$\}$
F	$\{\texttt{num}, \texttt{id}\}$	$\{+, -, *, /, \$\}$
$\texttt{id}$	$\{\texttt{id}\}$	–
$\texttt{num}$	$\{\texttt{num}\}$	–
$*$	$\{*\}$	–
$/$	$\{/\}$	–
$+$	$\{+\}$	–
$-$	$\{-\}$	–

	id	num	+	–	*	/	$
S	$S \to E$	$S \to E$	–	–	–	–	–
E	$E \to TE'$	$E \to TE'$	–	–	–	–	–
E'	–	–	$E' \to +E$	$E' \to -E$	–	–	$E' \to \varepsilon$
T	$T \to FT'$	$T \to FT'$	–	–	–	–	–
T'	–	–	$T' \to \varepsilon$	$T' \to \varepsilon$	$T' \to *T$	$T' \to /T$	$T' \to \varepsilon$
F	$F \to \texttt{id}$	$F \to \texttt{num}$	–	–	–	–	–

Building the tree

Again, we insert code at the right points:

```
tos ← 0
Stack[tos] ← EOF
Stack[++tos] ← root node
Stack[++tos] ← Start Symbol
token ← next_token()
repeat
    X ← Stack[tos]
    if X is a terminal or EOF then
        if X = token then
            pop X
            token ← next_token()
            pop and fill in node
        else error()
    else /* X is a non-terminal */
```
$$\text{if } M[\text{X,token}] = X \to Y_1 Y_2 \cdots Y_k \text{ then}$$
```
            pop X
            pop node for X
            build node for each child and
            make it a child of node for X
```
$$\text{push } n_k, Y_k, n_{k-1}, Y_{k-1}, \cdots, n_1, Y_1$$
```
        else error()
until X = EOF
```

A grammar that is not LL(1)

$$\langle stmt \rangle \quad ::= \quad \texttt{if} \ \langle expr \rangle \ \texttt{then} \ \langle stmt \rangle$$
$$| \quad \texttt{if} \ \langle expr \rangle \ \texttt{then} \ \langle stmt \rangle \ \texttt{else} \ \langle stmt \rangle$$
$$| \quad \ldots$$

Left-factored:

$$\langle stmt \rangle \quad ::= \quad \texttt{if} \ \langle expr \rangle \ \texttt{then} \ \langle stmt \rangle \ \langle stmt' \rangle \mid \ldots$$
$$\langle stmt' \rangle \quad ::= \quad \texttt{else} \ \langle stmt \rangle \mid \varepsilon$$

Now, $\text{FIRST}(\langle stmt' \rangle) = \{\varepsilon, \texttt{else}\}$
Also, $\text{FOLLOW}(\langle stmt' \rangle) = \{\texttt{else}, \$\}$
But, $\text{FIRST}(\langle stmt' \rangle) \bigcap \text{FOLLOW}(\langle stmt' \rangle) = \{\texttt{else}\} \neq \phi$

On seeing `else`, conflict between choosing

$$\langle stmt' \rangle ::= \texttt{else} \ \langle stmt \rangle \quad \text{and} \quad \langle stmt' \rangle ::= \varepsilon$$

$\Rightarrow$ grammar is not LL(1)!

The fix:

Put priority on $\langle stmt' \rangle ::= \texttt{else} \ \langle stmt \rangle$ to associate `else` with closest previous `then`.

Error recovery

Key notion:

- For each non-terminal, construct a set of terminals on which the parser can synchronize
- When an error occurs looking for A, scan until an element of SYNCH(A) is found

Building SYNCH:

1. $a \in \text{FOLLOW}(A) \Rightarrow a \in \text{SYNCH}(A)$
2. place keywords that start statements in SYNCH(A)
3. add symbols in FIRST(A) to SYNCH(A)

If we can't match a terminal on top of stack:

1. pop the terminal
2. print a message saying the terminal was inserted
3. continue the parse

(i.e., SYNCH$(a) = V_t - \{a\}$)

Some definitions

Recall

For a grammar G, with start symbol S, any string α such that $S \Rightarrow^* \alpha$ is a *sentential form*

- If $\alpha \in V_t^*$, then α is a *sentence* in $L(G)$

A *left-sentential form* is a sentential form that occurs in the leftmost derivation of some sentence.

A *right-sentential form* is a sentential form that occurs in the rightmost derivation of some sentence.

Bottom-up parsing

Goal:

>   *Given an input string w and a grammar G, construct a parse tree
>   by starting at the leaves and working to the root.*

The parser repeatedly matches a *right-sentential* form from the language
against the tree's upper frontier.

At each match, it applies a *reduction* to build on the frontier:

- each reduction matches an upper frontier of the partially built tree to
  the RHS of some production

- each reduction adds a node on top of the frontier

The final result is a rightmost derivation, in reverse.

Example

Consider the grammar

$$
\begin{array}{c|lcl}
1 & S & \rightarrow & \texttt{a}AB\texttt{e} \\
2 & A & \rightarrow & A\texttt{bc} \\
3 &   & | & \texttt{b} \\
4 & B & \rightarrow & \texttt{d}
\end{array}
$$

and the input string `abbcde`

Prod'n.	Sentential Form
3	a b bcde
2	a Abc de
4	aA d e
1	aABe
–	S

Scan the input and find valid sentential forms!

Handles

What are we trying to find?

A substring α of the tree's upper frontier that

> matches some production $A \rightarrow \alpha$ where reducing α to A is one step in the reverse of a rightmost derivation

We call such a string a *handle*.

Formally:

> In a right-sentential form $\alpha\beta w$, the string β is a handle for production $A \rightarrow \beta$

i.e., if $S \Rightarrow^*_{\mathrm{rm}} \alpha A w \Rightarrow_{\mathrm{rm}} \alpha\beta w$ then β is a handle for $A \rightarrow \beta$ in $\alpha\beta w$

All right-sentential forms have a suffix containing only terminal symbols.

The handle $A \to \beta$ in the parse tree for $\alpha\beta w$

Handles

Theorem:

If G is unambiguous then every right-sentential form has a unique handle.

Proof: (by definition)

1. G is unambiguous $\Rightarrow$ rightmost derivation is unique

2. $\Rightarrow$ a unique production $A \rightarrow \beta$ applied to take γ_{i-1} to γ_i

3. $\Rightarrow$ a unique position k at which $A \rightarrow \beta$ is applied

4. $\Rightarrow$ a unique handle $A \rightarrow \beta$

Example

The left-recursive expression grammar   (*original form*)

1	$\langle goal \rangle$	$::= \langle expr \rangle$
2	$\langle expr \rangle$	$::= \langle expr \rangle + \langle term \rangle$
3		$\mid \langle expr \rangle - \langle term \rangle$
4		$\mid \langle term \rangle$
5	$\langle term \rangle$	$::= \langle term \rangle * \langle factor \rangle$
6		$\mid \langle term \rangle / \langle factor \rangle$
7		$\mid \langle factor \rangle$
8	$\langle factor \rangle$	$::= \texttt{num}$
9		$\mid \texttt{id}$

Prod'n.	Sentential Form
–	$\langle goal \rangle$
1	$\underline{\langle expr \rangle}$
3	$\underline{\langle expr \rangle} - \langle term \rangle$
5	$\langle expr \rangle - \underline{\langle term \rangle * \langle factor \rangle}$
9	$\langle expr \rangle - \langle term \rangle * \underline{\texttt{id}}$
7	$\langle expr \rangle - \underline{\langle factor \rangle} * \texttt{id}$
8	$\langle expr \rangle - \underline{\texttt{num}} * \texttt{id}$
4	$\underline{\langle term \rangle} - \texttt{num} * \texttt{id}$
7	$\underline{\langle factor \rangle} - \texttt{num} * \texttt{id}$
9	$\underline{\texttt{id}} - \texttt{num} * \texttt{id}$

Handle-pruning

The process to construct a bottom-up parse is called *handle-pruning*.

To construct a rightmost derivation

$$S = \gamma_0 \Rightarrow \gamma_1 \Rightarrow \gamma_2 \Rightarrow \cdots \Rightarrow \gamma_{n-1} \Rightarrow \gamma_n = w$$

we set i to n and apply the following simple algorithm

```
for i = n downto 1
```

1. `find the handle` $A_i \to \beta_i$ `in` γ_i

2. `replace` β_i `with` A_i `to generate` γ_{i-1}

This takes $2n$ steps, where n is the length of the derivation

Stack implementation

One scheme to implement a handle-pruning, bottom-up parser is called a *shift-reduce* parser.

Shift-reduce parsers use a *stack* and an *input buffer*

1. initialize stack with $

2. Repeat until the top of the stack is the goal symbol and the input token is $

    a) *find the handle*
       if we don't have a handle on top of the stack, *shift* an input symbol onto the stack

    b) *prune the handle*
       if we have a handle for $A \rightarrow \beta$ on the stack, *reduce*:

       i) pop $| \beta |$ symbols off the stack

       ii) push A onto the stack

Example: back to $x - 2 * y$

1. $\langle goal \rangle \ ::= \langle expr \rangle$
2. $\langle expr \rangle \ ::= \langle expr \rangle + \langle term \rangle$
3. $\qquad\qquad | \ \langle expr \rangle - \langle term \rangle$
4. $\qquad\qquad | \ \langle term \rangle$
5. $\langle term \rangle \ ::= \langle term \rangle * \langle factor \rangle$
6. $\qquad\qquad | \ \langle term \rangle / \langle factor \rangle$
7. $\qquad\qquad | \ \langle factor \rangle$
8. $\langle factor \rangle ::= \texttt{num}$
9. $\qquad\qquad | \ \texttt{id}$

Stack	Input	Action
$	id $-$ num $*$ id	shift
$id	$-$ num $*$ id	reduce 9
$\langle factor \rangle$	$-$ num $*$ id	reduce 7
$\langle term \rangle$	$-$ num $*$ id	reduce 4
$\langle expr \rangle$	$-$ num $*$ id	shift
$\langle expr \rangle -$	num $*$ id	shift
$\langle expr \rangle -$ num	$*$ id	reduce 8
$\langle expr \rangle - \langle factor \rangle$	$*$ id	reduce 7
$\langle expr \rangle - \langle term \rangle$	$*$ id	shift
$\langle expr \rangle - \langle term \rangle *$	id	shift
$\langle expr \rangle - \langle term \rangle * $ id		reduce 9
$\langle expr \rangle - \langle term \rangle * \langle factor \rangle$		reduce 5
$\langle expr \rangle - \langle term \rangle$		reduce 3
$\langle expr \rangle$		reduce 1
$\langle goal \rangle$		accept

1. *Shift until top of stack is the right end of a handle*

2. *Find the left end of the handle and reduce*

5 shifts + 9 reduces + 1 accept

Shift-reduce parsing

Shift-reduce parsers are simple to understand

A shift-reduce parser has just four canonical actions:

1. *shift* — next input symbol is shifted onto the top of the stack

2. *reduce* — right end of handle is on top of stack;
    locate left end of handle within the stack;
    pop handle off stack and push appropriate non-terminal LHS

3. *accept* — terminate parsing and signal success

4. *error* — call an error recovery routine

But how do we know

- that there is a complete handle on the stack?

- which handle to use?

LR parsing: key insight

Recognize handles with a DFA [Knuth1965]

- DFA transitions shift states instead of symbols

- accepting states trigger reductions

LR parsing

The skeleton parser:

```
push s_0
token ← next_token()

repeat forever
   s ← top of stack

   if action[s,token] = "shift s_i" then
      push s_i
      token ← next_token()

   else if action[s,token] = "reduce A → β"
      then
      pop |β| states
      s' ← top of stack
      push goto[s',A]

   else if action[s, token] = "accept" then
      return

   else error()
```

This takes k shifts, l reduces, and 1 accept, where k is the length of the input string and l is the length of the reverse rightmost derivation

Example tables

state	ACTION				GOTO		
	`id`	$+$	$*$	`$`	$\langle \text{expr} \rangle$	$\langle \text{term} \rangle$	$\langle \text{factor} \rangle$
0	s4	–	–	–	1	2	3
1	–	–	–	acc	–	–	–
2	–	s5	–	r3	–	–	–
3	–	r5	s6	r5	–	–	–
4	–	r6	r6	r6	–	–	–
5	s4	–	–	–	7	2	3
6	s4	–	–	–	–	8	3
7	–	–	–	r2	–	–	–
8	–	r4	–	r4	–	–	–

The Grammar

1	$\langle \text{goal} \rangle$	::=	$\langle \text{expr} \rangle$
2	$\langle \text{expr} \rangle$	::=	$\langle \text{term} \rangle + \langle \text{expr} \rangle$
3		|	$\langle \text{term} \rangle$
4	$\langle \text{term} \rangle$	::=	$\langle \text{factor} \rangle * \langle \text{term} \rangle$
5		|	$\langle \text{factor} \rangle$
6	$\langle \text{factor} \rangle$	::=	`id`

Note: This is a simple little right-recursive grammar; *not* the same as in previous lectures.

Example using the tables

Stack	Input	Action
$ 0	id∗ id+ id$	s4
$ 0 4	∗ id+ id$	r6
$ 0 3	∗ id+ id$	s6
$ 0 3 6	id+ id$	s4
$ 0 3 6 4	+ id$	r6
$ 0 3 6 3	+ id$	r5
$ 0 3 6 8	+ id$	r4
$ 0 2	+ id$	s5
$ 0 2 5	id$	s4
$ 0 2 5 4	$	r6
$ 0 2 5 3	$	r5
$ 0 2 5 2	$	r3
$ 0 2 5 7	$	r2
$ 0 1	$	acc

LR(k) grammars

Informally, we say that a grammar G is LR(k) if, given a rightmost derivation

$$S = \gamma_0 \Rightarrow \gamma_1 \Rightarrow \gamma_2 \Rightarrow \cdots \Rightarrow \gamma_n = w,$$

we can, for each right-sentential form in the derivation,

1. *isolate the handle of each right-sentential form*, and

2. *determine the production by which to reduce*

by scanning γ_i from left to right, going at most k symbols beyond the right end of the handle of γ_i.

LR(k) grammars

Formally, a grammar G is LR(k) iff.:

1. $S \Rightarrow^*_{\mathrm{rm}} \alpha A w \Rightarrow_{\mathrm{rm}} \alpha \beta w$, and

2. $S \Rightarrow^*_{\mathrm{rm}} \gamma B x \Rightarrow_{\mathrm{rm}} \alpha \beta y$, and

3. $\mathrm{FIRST}_k(w) = \mathrm{FIRST}_k(y)$

impliers $\alpha A y = \gamma B x$

i.e., Assume sentential forms $\alpha \beta w$ and $\alpha \beta y$, with common prefix $\alpha \beta$ and common k-symbol lookahead $\mathrm{FIRST}_k(y) = \mathrm{FIRST}_k(w)$, such that $\alpha \beta w$ reduces to $\alpha A w$ and $\alpha \beta y$ reduces to $\gamma B x$.

But, the common prefix means $\alpha \beta y$ also reduces to $\alpha A y$, for the same result.

Thus $\alpha A y = \gamma B x$.

Why study LR grammars?

LR(1) grammars are often used to construct parsers.

We call these parsers LR(1) parsers.

- virtually all context-free programming language constructs can be expressed in an LR(1) form
- LR grammars are the most general grammars parsable by a deterministic, bottom-up parser
- efficient parsers can be implemented for LR(1) grammars
- LR parsers detect an error as soon as possible in a left-to-right scan of the input
- LR grammars describe a proper superset of the languages recognized by predictive (i.e., LL) parsers

  LL(k)**:** recognize use of a production $A \rightarrow \beta$ seeing first k symbols derived from β

  LR(k)**:** recognize the handle β after seeing everything derived from β plus k lookahead symbols
